ABSTRACT

Waste-rock material produced at historic metal mines contains elevated concentrations of potentially toxic trace elements. Two types of mine waste were examined in this study: sintered waste rock and slag. The samples were collected from the Elizabeth and Ely mines in the Vermont copper belt (Besshi-type massive sulfide deposits), from the Copper Basin mining district near Ducktown, Tennessee (Besshi-type massive sulfide deposits), and from the Clayton silver mine in the Bayhorse mining district, Idaho (polymetallic vein and replacement deposits). The data in this report are presented as a compilation with minimal interpretation or discussion. A detailed discussion and interpretation of the slag data are presented in a companion paper. Data collected from sintered waste rock and slag include: (1) bulk rock chemistry, (2) mineralogy, (3) and the distribution of trace elements among phases for the slag samples. In addition, the reactivity of the waste material under surficial conditions was assessed by examining secondary minerals formed on slag and by laboratory leaching tests using deionized water and a synthetic solution approximating precipitation in the eastern United States.

INTRODUCTION

Abandoned mines and smelter sites commonly have mine-waste material including waste rock, flotation tailings, and slag, which contain elevated concentrations of trace elements such as Cu, Zn, and Pb. These potentially toxic trace metals may be released into the environment through natural weathering processes and have adverse effects on water quality. In this study, mine-waste material including slag and sintered waste rock was characterized by determining bulk major and trace-element chemistry, and mineral chemistry. Also, the leachability of metals was examined using a modified version of the field-leach test developed by Hageman and Briggs (2000) for the characterization of mine waste.

The suite of samples studied was collected from four mine sites. The Elizabeth and Ely mines in the Vermont copper belt in Orange County, Vermont, exploited Besshi-type massive sulfide deposits. The ores consisted of pyrrhotite, chalcopyrite, and minor sphalerite and pyrite (Offield and Slack, 1993; Slack and others, 2001). The Elizabeth mine was in operation from 1809 to 1958, and the Ely mine operated from the 1850's to 1905 (Kierstead, 2001). A variety of samples of waste rock and slag were examined from these two mines. Summaries of the geology, environmental geochemistry, and mining history of the Elizabeth and Ely mines can be found in the Society of Economic Geologists Guidebook Series, volume 35 (Crowley and others, 2001; Hammarstrom and others, 2001a; Hammarstrom and others, 2001b; Hathaway and others, 2001; Kierstead, 2001; Seal and others, 2001a; Seal and others, 2001b; and Slack and others, 2001).

Like the deposits in the Vermont copper belt, the Ducktown mining district in Polk County, Tennessee, exploited Besshi-type massive sulfide deposits. The primary ore minerals were pyrrhotite, subordinate pyrite, with minor chalcopyrite, sphalerite, magnetite, and sparse galena (Magee, 1968). The Ducktown mining district operated

from 1847 to 1987. Granulated slag (quenched in water) and calcine (ore which has been crushed, concentrated, and roasted) were collected and characterized from this site.

In contrast to the Besshi-type massive sulfide deposits of Vermont and Tennessee, the deposits in the Bayhorse mining district, Idaho, include polymetallic vein and replacement deposits (Hammarstrom and others, 2002). The major sulfide minerals are galena, sphalerite, pyrite, tetrahedrite, and chalcopyrite (Ross, 1937). A sample of air-cooled slag was collected from the Clayton smelters, which operated intermittently from the 1880's to 1902, reopened in 1913, and then again in 1935. This site smelted ore from several mines within the mining districts of Greyhound Ridge, Seafoam, Germania Basin, and Bayhorse (Wells, 1983).

This report forms the detailed analytical basis for the interpretation and discussion of petrographic and geochemical data by Piatak and others (2004). Additional data and interpretations for sintered waste rock from the Elizabeth and Ely mines, calcine from Ducktown, and two pot slag samples are included in this report.

METHODS

The bulk chemical composition of the solid samples was determined using inductively coupled plasma-atomic emission spectrometry (ICP-AES), and inductively coupled plasma-mass spectrometry (ICP-MS) following acid-digestion by a mixture of HCl-HNO₃-HClO₄-HF in USGS laboratories in Denver, Colorado (Crock and others, 1999). Also, major oxide content was measured using wavelength dispersive X-ray fluorescence spectroscopy (WD-XRF) following fusion in a mixture of LiBO₂ and LiB₄O₇. Interpretation in text is based on ICP-MS for minor elements and on ICP-AES for major elements, except SiO₂ content, for which WD-XRF results are used. Total sulfur was measured using a LECO S analyzer. WD-XRF and LECO S analyses were preformed by XRAL Laboratories, Ontario, Canada.

Mineralogical identification and the distribution of trace metals within phases was determined using transmitted- and reflected-light microscopy, X-ray diffraction analysis (XRD), scanning electron microscopy (SEM), and electron-microprobe analysis (EPMA) in USGS laboratories in Reston, Virginia. XRD was performed using a Scintag X1 automated powder diffractometer equipped with a Peltier detector with CuK α radiation. The XRD patterns were analyzed using Material Data Inc.'s JADE software and standard reference patterns (International Centre for Diffraction Data, 1997). SEM analyses were performed with a JEOL JSM-840 SEM equipped with a backscattered electron detector, a secondary electron detector, and a PGT X-ray energy-dispersive system. Spectra were collected using an accelerating voltage of 15-20 kV, and a specimen current of 1 to 10 nA. A JEOL JXA 8900A microprobe equipped with five wavelength-dispersive spectrometers was operated at an accelerating voltage of 15-20 kV, a beam current of 20-30 nA, and a beam diameter of up to 5 μ m. The analyses were corrected for electron beam/matrix, and instrumental drift and dead time using either a ZAF or a Phi-Rho-Z-CITZAF scheme supplied with the JEOL instrument software.

A modified version of a Field-Leach Test developed by Hageman and Briggs (2000) was preformed on splits of the samples in USGS laboratories in Reston, Virginia. The samples were crushed and sieved to a diameter of less than 2 mm. Each sample was

combined with either deionized water (DIW) or a solution that approximates eastern United States precipitation (ESP) at a solution to sample ratio of 20:1. A mixture of sulfuric acid and nitric acid was added to the deionized water to adjust the pH to 4.2 ± 0.1 , to produce synthetic eastern precipitation solution (U.S. E.P.A., 1994). The mixtures were shaken initially for one minute and after 24 hours filtered through $0.45 \mu\text{m}$ nitrocellulose filters. Filtered splits were analyzed for cations by ICP-MS and ICP-AES, and for anions (sulfate and chloride) by ion chromatography (IC) in USGS laboratories in Denver, Colorado, and Ocala, Florida, respectively.

SAMPLE DESCRIPTION

Pot slag (air-cooled) and sintered waste rock were collected from the Elizabeth and Ely mines (Figure 1 and Table 1). The molten slag produced by smelting the ore was poured into pots and then dumped in waste piles. Examples of these slag-pot casts are shown in Figure 2A and B. Two of the pot slag samples from the Elizabeth mine were subdivided as rind (first few centimeters from the chilled margin) and core, and were analyzed separately. Also, texturally distinctive splits of samples 01JH27 (Elizabeth), 01JH28 (Elizabeth), and 01JH34 (Ely) were examined separately. In contrast to the pot slag samples, the sintered waste rock consists of both ore and host rock, which was broken or crushed and heated without melting (Figure 2C).

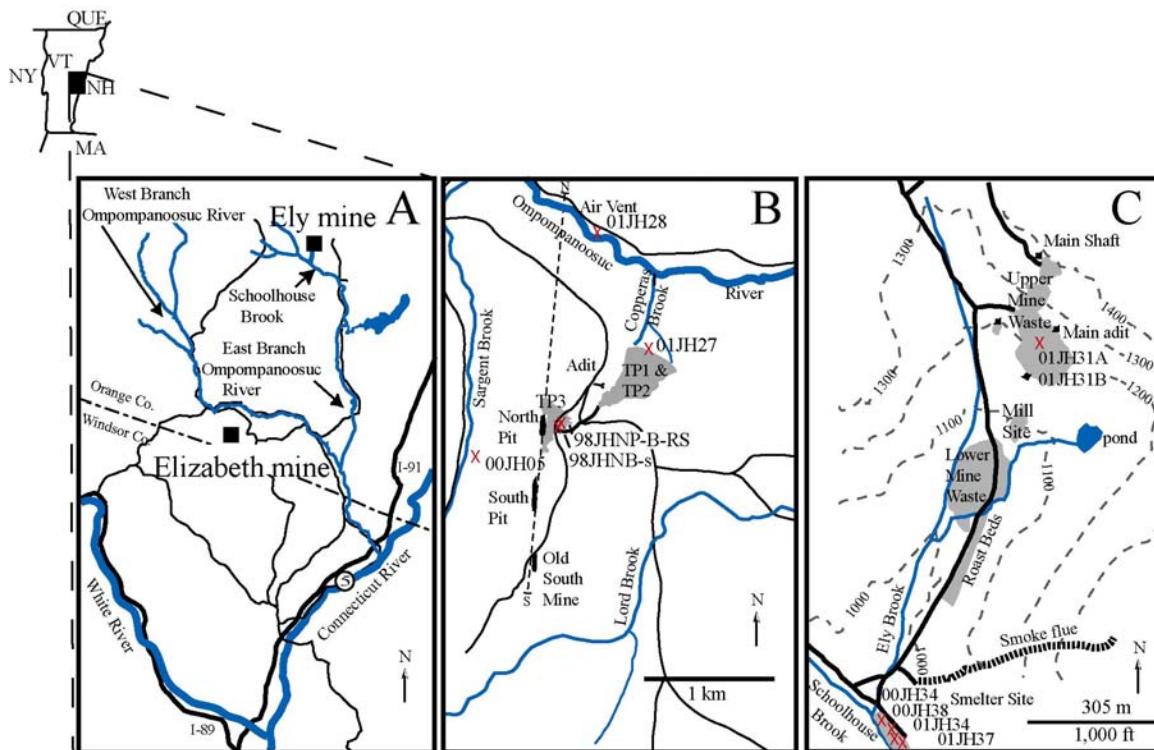

Figure 1. Locations of study areas showing sample sites in Vermont. A. Locations of Elizabeth and Ely mines. B. Sketch map of Elizabeth mine site. C. Sketch map of Ely mine site. Sample sites designated with a red "X".

Table 1. Sample descriptions.

Sample number	Mining district	Mine	Type	Sample description	Mineralogy	Comments	Location description	Smelter site	Smelting date
98JHNP-B-RS	Vermont copper belt	Elizabeth	waste rock	red; oxidized rock	quartz, feldspar, spinel, hematite, jarosite, minor mica	sintered rock	Tailings pile 3 (TP3)	n.a. ^a	n.a.

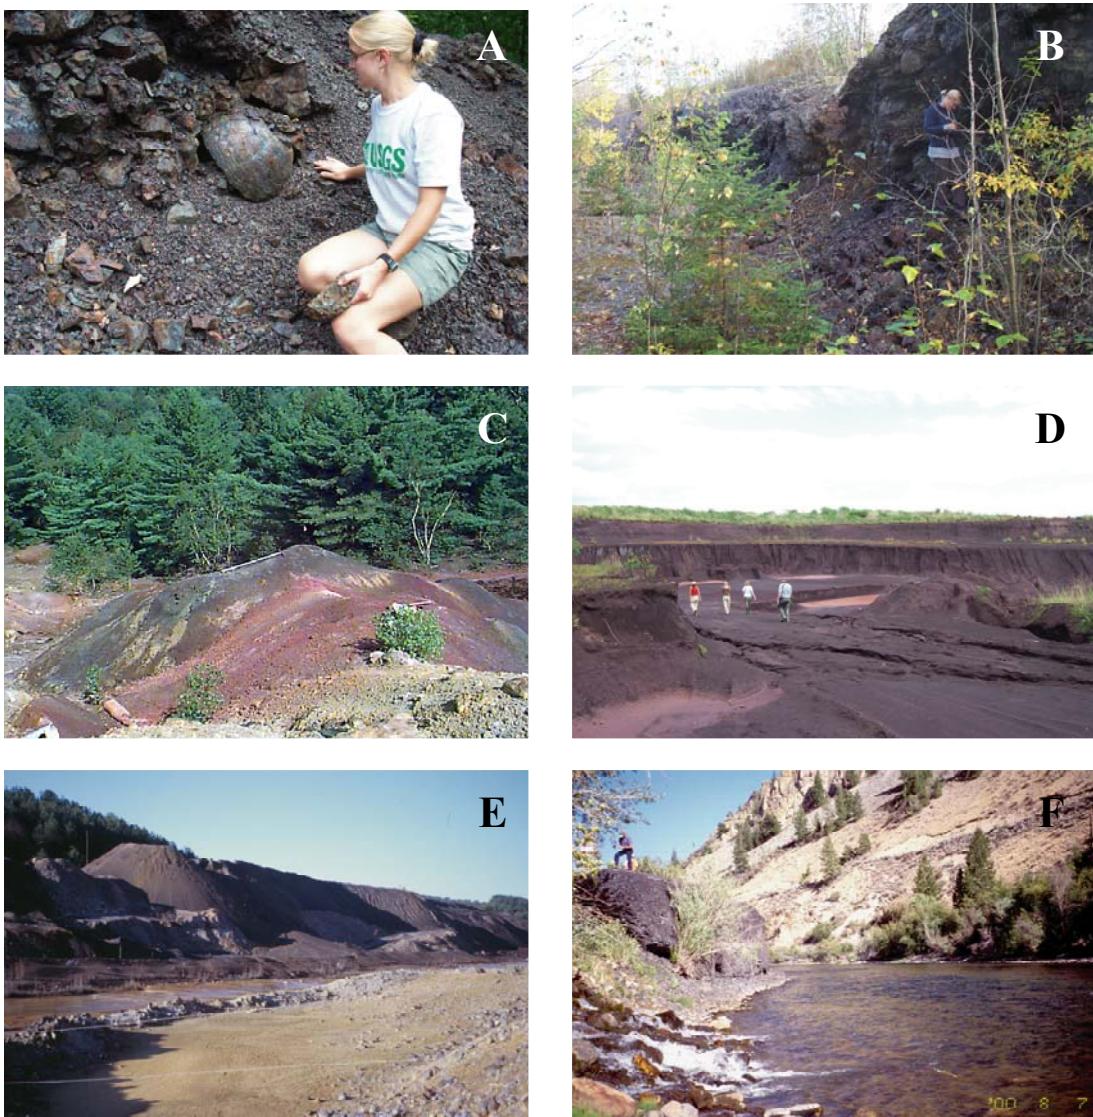

Figure 2. Representative photographs of sample sites. A. Slag pile (sample 00JH05) at the Elizabeth mine. B. Slag pile along Schoolhouse Brook at the Ely mine. C. Sintered waste rock from the Elizabeth mine, TP3 area. The black is 98JHNPPB-s and the red is 98JHNPPB-RS. D. Low-sulfur calcine (sample 01CB23) at Ducktown. E. Granulated slag pile (sample 01CB25) along Davis Mill Creek at Ducktown. F. Black pile on left side of the river is air-cooled slag at the Clayton smelter site, sample 53JH00.

Low-sulfur calcine and granulated slag were collected from the Ducktown mining district (Figure 3). Mineralogical characterization and environmental impacts of waste at this site is discussed by Moyer and others (2000; 2002). The calcine is crushed, concentrated, and roasted ore (Figure 2D). In contrast, the granulated slag is the product of melting the calcine with a flux, removing the Cu matte, and cooling the waste material

in a stream of flowing water, which caused it to fracture into sand-sized particles (Anonymous-Polk County Publishers). A pile of granulated slag is located along Davis Mill Creek (Figure 2E).

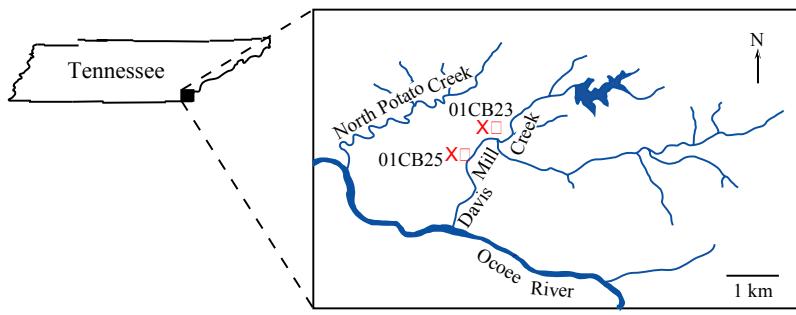

Figure 3. Location of calcine (01CB23) and granulated slag (01CB25) samples collected from the Ducktown mining district. Sample sites are designated with a red "X".

An air-cooled slag sample was collected from the Clayton smelter site (Figure 4). The slag was dumped directly on the banks of the Salmon River (Figure 2F).

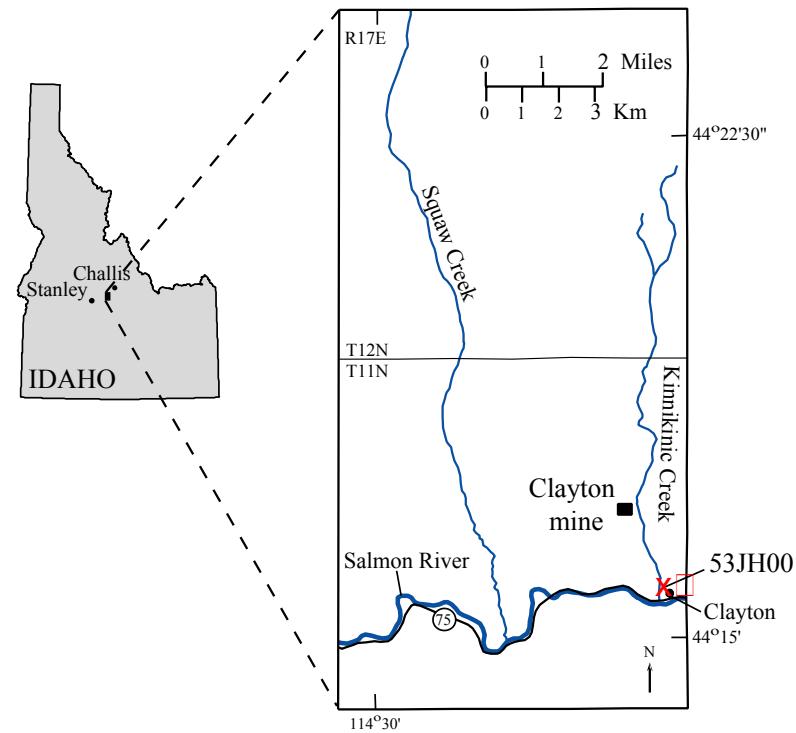

Figure 4. Location of Clayton, Idaho, smelter site and slag sample 53JH00 (designated with a red "X").

BULK-ROCK CHEMISTRY

The bulk chemical analyses indicate that the chemical compositions of the samples are heterogeneous (Table 2). The bulk chemistry of the samples is plotted on the FeO-Al₂O₃-SiO₂ and CaO-FeO-SiO₂ ternary diagrams in Figures 5A and B, respectively. Most samples are composed primarily of oxides of Fe and Si with varying amounts of Al and Ca. The calcine (01CB23) from Ducktown is an exception and is predominantly ferric iron oxide (Fe₂O₃). The waste-rock samples from the Ely mine contain higher concentrations of SiO₂ and lower concentrations of FeO compared to the pot slag samples. In contrast, the pot slag samples from the Elizabeth mine plot near or between the waste rock samples (Figure 5A and B). In general, the samples collected from Vermont contain higher concentrations of Al, K, and Na compared with the Ducktown and Clayton samples. Slag samples 01JH27 (Elizabeth) and 53JH00 (Clayton) contain the highest concentrations of Ca (4.1 wt. % and 3.1 wt. %, respectively), compared to all other samples (<1.9 wt. %).

The samples also display variations in trace-element concentrations (Table 2). The calcine and granulated slag from Ducktown are low in Cu (1,400 mg/kg and 2,000 mg/kg, respectively) compared to as much as 13,500 mg/kg for slag from Vermont and 7,550 mg/kg for slag from the Clayton smelter site. Several slag samples from the Vermont copper belt contain high concentrations of Co such as 00JH34 (922 mg/kg), 01JH34 (716 mg/kg), and 00JH05 (600 mg/kg). Sample 01JH27 contains the highest concentration of Cr (276 mg/kg). The Clayton smelter slag contains anomalous concentrations of several elements compared to the other samples. These elements include the following: Ag (200 mg/kg), As (555 mg/kg), Mn (22,000 mg/kg), Pb (63,000 mg/kg), Sb (1,710 mg/kg), Sn (363 mg/kg), Sr (285 mg/kg), W (175 mg/kg), and Zn (19,700 mg/kg).

MINERALOGY

Vermont copper belt

Slag

Slag samples from the Elizabeth and Ely mines are composed of olivine-group minerals, glass, spinels, sulfides, native metals, and quartz. Many of the samples display an increase in grain size from glassy rinds to megascopically crystalline interiors. For example, Figure 6A illustrates a glassy rind (top of photomicrograph) and an increase in the grain size of olivines away from this rind (bottom of photomicrograph). Flow textures are also evident in slag deposited in the molten state. The olivine-group minerals are a dominant phase in most samples and commonly display spinifex texture within a glassy or finely crystalline matrix. Radial and parallel olivine laths up to several centimeters long observed in slag samples suggest rapid cooling (Figure 6B, C, and D). Less commonly, olivine crystals in the interior of a sample are subhedral to euhedral (Figure 6E). The individual microprobe analyses and averages for olivine in each slag

Table 2. Geochemical data for bulk samples. See Crock and others (1999) for explanation of methods.

^a data from Hammarstrom and others (1999).^b samples were analyzed by ICP-AES in 2001 and reanalyzed by ICP-AES and ICP-MS in 2002. Discussion in text is based on 2002 analyses.^c WD-WRF results are a minimum for 53JH00 due to analytical interference caused by the high Pb and Zn concentrations.^d not analyzed or not available^e Total Fe reported as Fe₂O₃ and was recalculated as FeO for slag samples based on mineralogical observations.

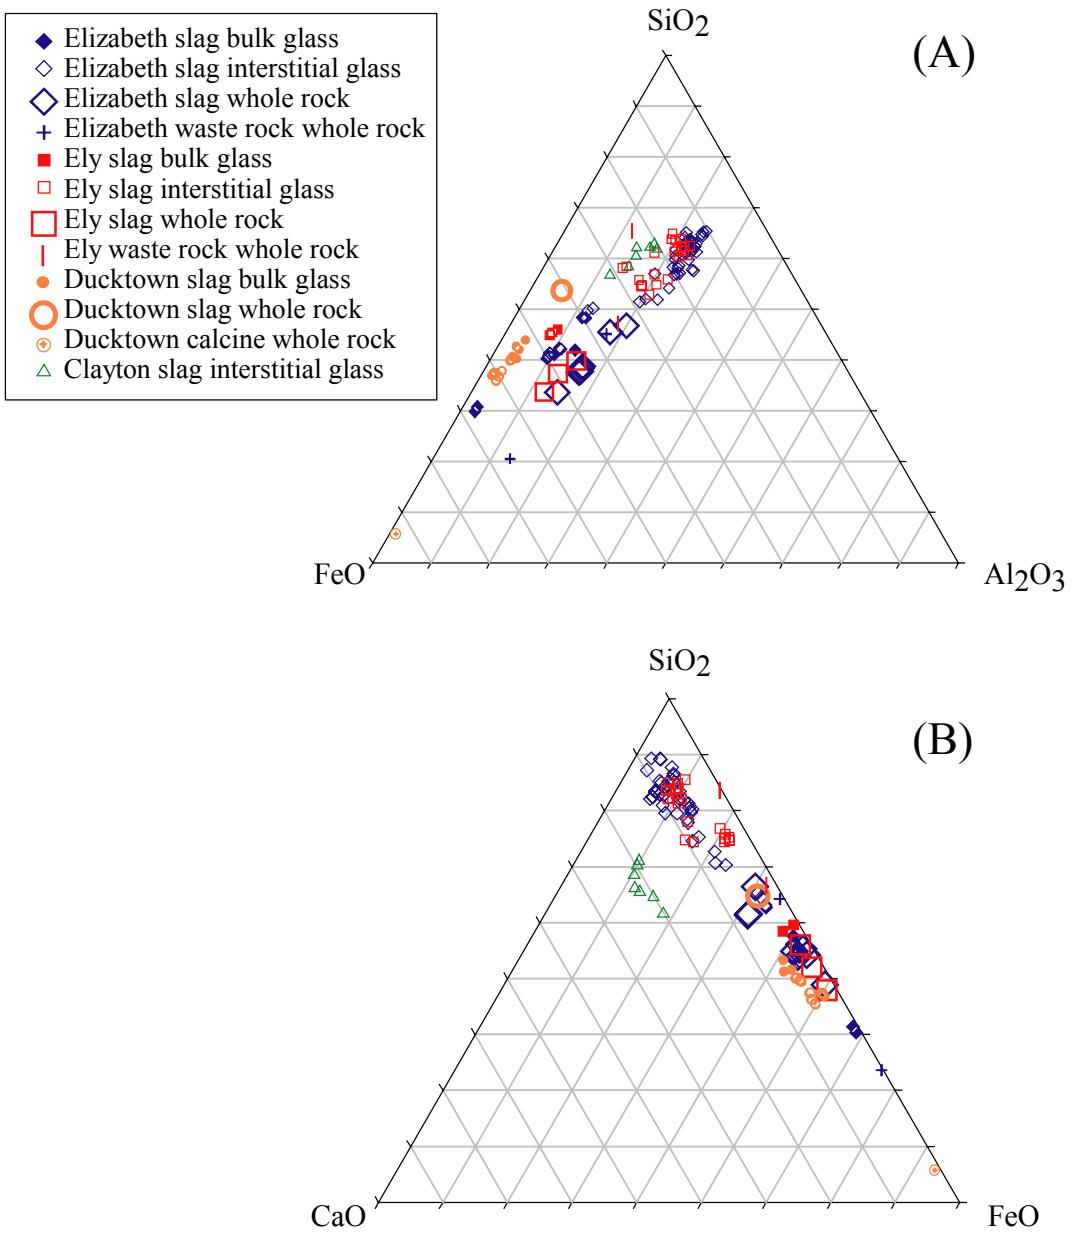

Figure 5. Glass compositions and bulk chemical compositions on A. FeO-Al₂O₃-SiO₂ and B. CaO-FeO-SiO₂ ternary diagrams. Bulk glass analyses for slag are shown with small filled symbols, interstitial glass analyses for slag with small open symbols, whole rock analyses for slag with large open symbols and whole rock analyses for waste rock with miscellaneous symbols.

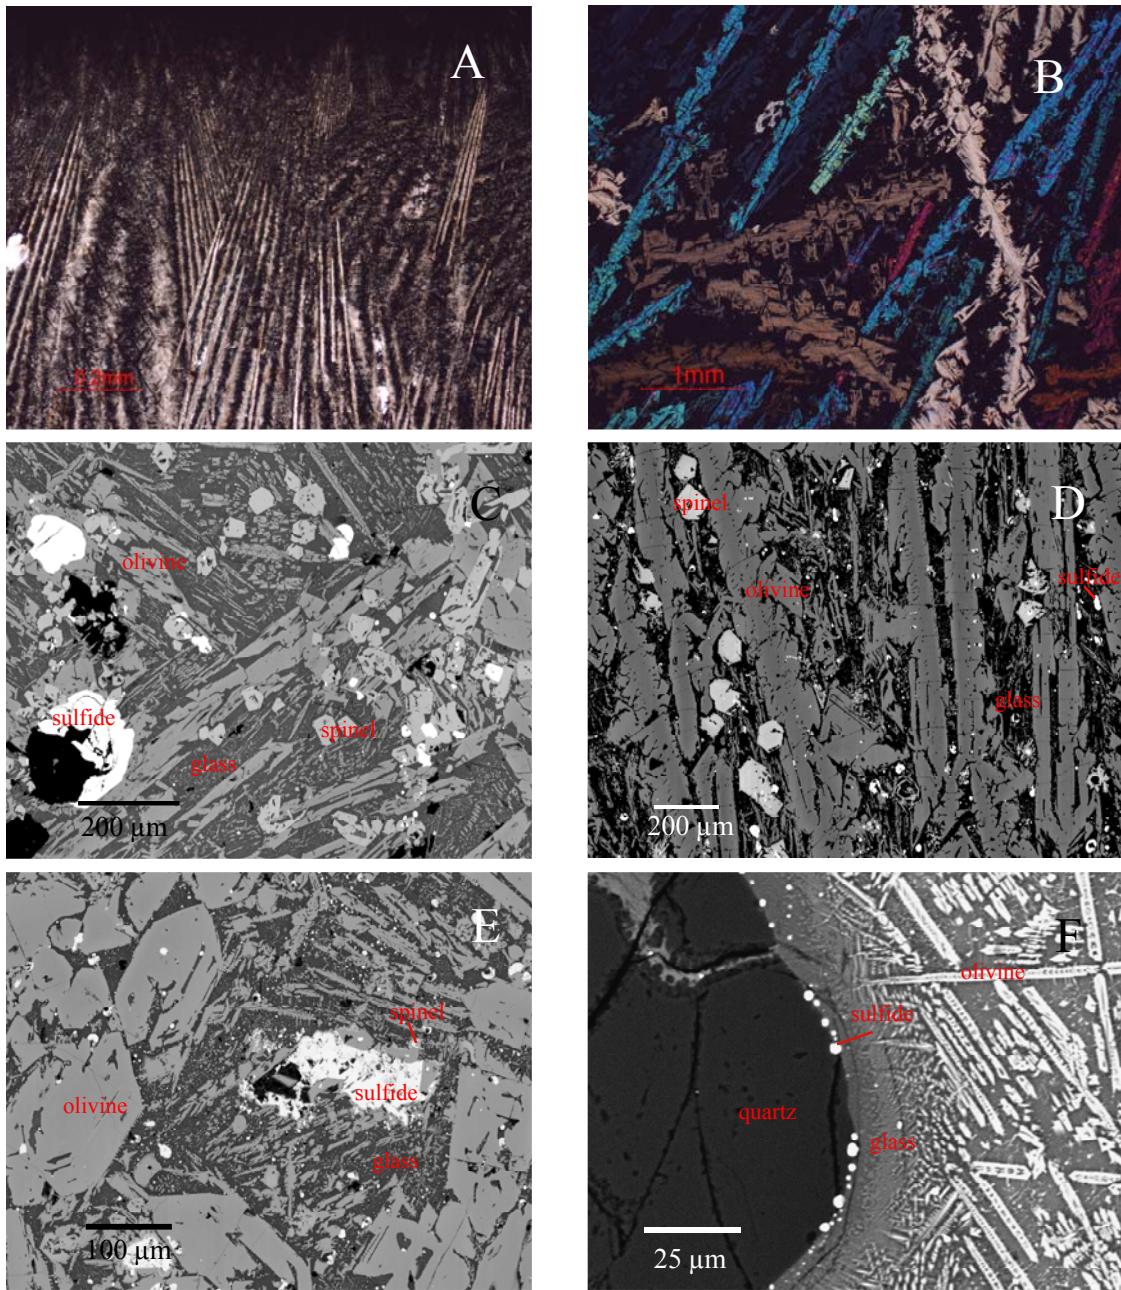

Figure 6. Photomicrographs of slag samples from the Elizabeth and Ely mines. A. Transmitted light photomicrograph of 01JH37rind showing glassy chilled margin and an increase in olivine laths away from rind. B. Transmitted light photomicrograph in crossed polars of 01JH34a illustrating high birefringence of radially-oriented skeletal olivines. C. Backscattered scanning electron (BSE) photomicrograph of 01JH28core. D. BSE photomicrograph of 01JH34a. E. BSE photomicrograph of 00JH38. F. BSE photomicrograph of 01JH28.

sample from the Elizabeth and Ely mines are given in Table 3. As shown in Figure 7, the compositions of olivine-group minerals lie along the forsterite-fayalite join. The olivine from the Elizabeth mine is more Mg-rich than that from the Ely mine. Also, the olivines from the Vermont copper belt contain up to 1.17 wt. % ZnO.

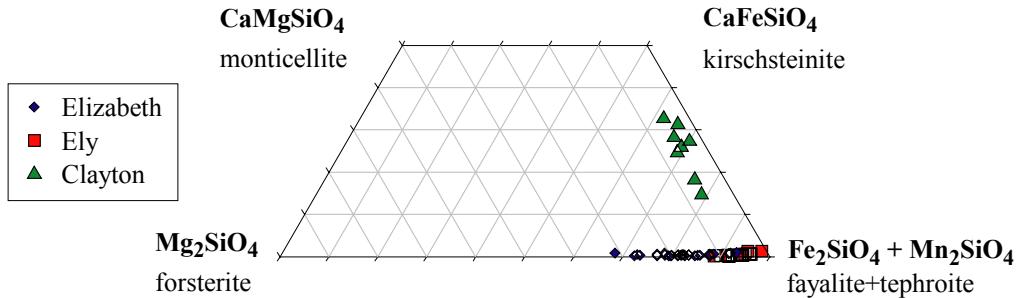

Figure 7. Olivine compositions in the forsterite-(fayalite+tephroite)-kirschsteinite-monticellite quadrilateral diagram.

The glass phase in the slag samples was categorized as either interstitial or bulk glass. The interstitial glass is the matrix material (Figure 6B-E) and the bulk glass refers to either surface glass such as the rind for a pot-slag cast (Figure 6A), chilled margins (Figure 6F), or areas that consist of only glass, such as those exhibiting flow textures, without crystalline phases. The bulk glass contains higher concentrations of Fe, and lower concentrations of Si and Al when compared to the interstitial glass (Figure 5 and Table 4). In general, bulk glass has higher concentrations of Mg, S, and Zn and lower concentrations of Na, K, and Ca relative to interstitial glass (Figure 5 and Table 4).

One slag sample from the Elizabeth mine contains quartz inclusions up to 1 mm in diameter (Figure 6F). The grain size of the olivine laths decreases towards the quartz grain. The quartz grain is thus interpreted as a small inclusion from the silica-brick used to line the smelting furnace.

Spinel in slag is euhedral to subhedral, and ranges from a micrometer to approximately a hundred micrometers in diameter (Figure 6C-E). Individual microprobe analyses and averages for spinel in each slag sample are given in Table 5. The divalent site is dominated by over 90 % ferrous iron and up to 5.3 % Zn with the rest of the site containing Mg with very minor Ca and Mn (Figure 8A). The trivalent site includes cations with a +3 valence and +4 valence, occurring in coupled substitution. This site is predominantly Fe and Al, with minor Ti, Si, and Cr (Figure 8B). The composition of the spinel in Vermont samples lies between magnetite and hercynite. In several samples, the spinels exhibit zoning. For example, the cores of a few spinel grains in sample 00JH05 contain higher concentrations of Cr than the rims, which are enriched in Al and Fe. In contrast, the core of the spinel in sample 01JH37 is enriched in Fe and Ti and depleted in Al relative to the rim.

Disseminated sulfides in slag are dominated by Fe and Cu and range from less than 1 μm to 500 μm in diameter (Figure 6C-F and Figure 9A). Sulfides occur as discrete grains or as admixtures of sulfides of various compositions and native metals.

Table 3. Electron-microprobe analyses of olivine and pyroxene in slag samples. Concentrations reported as weight percent.

^a Fe²⁺/Fe³⁺ ratio was estimated using site-occupancy constraints^b not determined

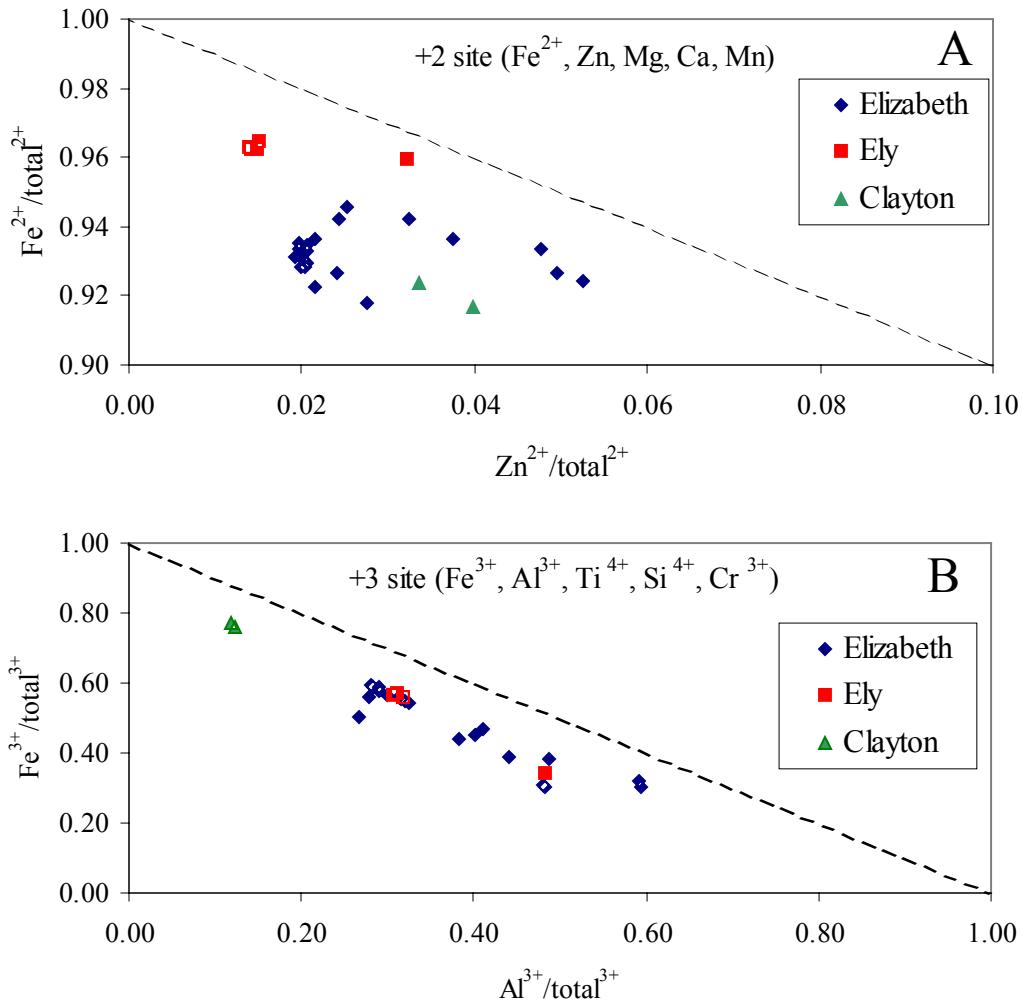

Figure 8. Composition of A. divalent and B. trivalent sites in spinel in slag samples. Appropriate valence distributions are calculated from electron-microprobe analyses assuming ideal stoichiometry. Diagonal line indicates full occupancy.

The compositions of many apparently single-phase grains (Table 6) are intermediate between discrete phases in the Cu-Fe-S system such as pyrrhotite, intermediate solid solution, and bornite-digenite, suggesting quenching at high temperatures (Cabri, 1973). Compositions tend to cluster around bornite and pyrrhotite. Many grains display small-scale exsolution as illustrated in Figure 9A and Figure 10. The concentrations of Cu, Fe, and S vary widely in a grain only 60 μm in diameter (Figure 10).

Table 6. Electron-microprobe analyses for sulfide, metallic phases, and miscellaneous compounds in slag. Concentrations as weight percent.

BSE photomicrographs of 53JH00 (Clayton).

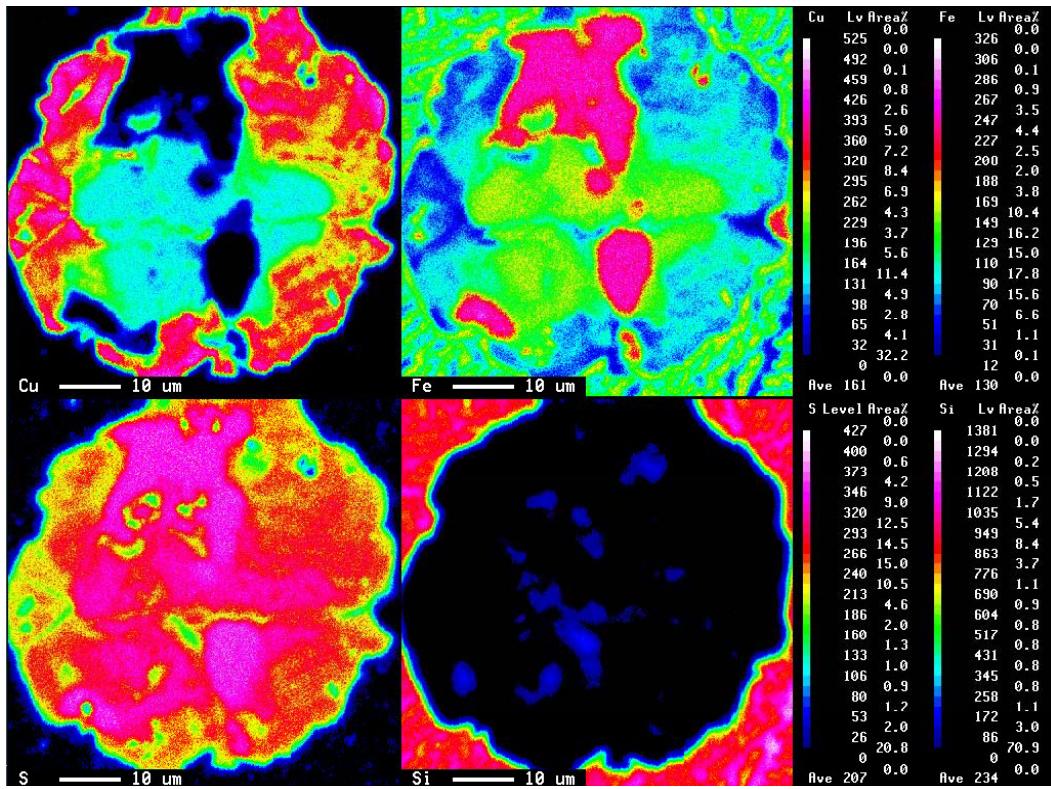

Figure 10. Electron-microprobe map illustrating the distribution of Cu, Fe, S, and Si in a sulfide bleb in sample 01JH34b slag from the Ely mine. Warmer colors indicate higher concentrations; cooler colors indicate lower concentrations.

Sintered waste rock

Two samples of sintered waste rock collected from the Elizabeth mine are oxidized red sinter (98JHNP-B-RS) composed of hematite, jarosite, spinel, quartz, plagioclase, and minor mica, and black sintered roasted ore (98JHNPB-s) composed of hematite, jarosite, quartz, and minor mica. One sample of sintered waste rock was collected from the Ely mine. This sample was divided into two splits based on textural variations, 01JH31A being vesicular. Both 01JH31A and 01JH31B contain hematite, spinel, sulfide, plagioclase and quartz. However, the amount of quartz in sample 01JH31B is especially high as reflected by the high concentration of SiO₂ (55.97 wt. %) in the bulk chemical analysis. Photomicrographs of sample 01JH31A (Figure 9B and C) in reflected and transmitted light illustrate hematite, sulfide, spinel, and quartz.

Ducktown mining district

Granulated slag

The granulated slag consists of conchoidally fractured bits of material less than a centimeter in diameter (Figure 9D). The sample contains glass, Fe-Cu sulfides, metallic

phases, and rare hematite. The composition of the glass is dominated by Fe and Si with minor Al (up to 4.11 wt. % Al_2O_3), Ca (up to 5.93 wt. % CaO), and S (up to 5.60 wt. % SO_3) (Figure 5 and Table 4). The compositions of the sulfides (Table 6) are intermediate between discrete phases in the Cu-Fe-S system and generally contain $\text{Fe} > \text{Cu}$. The sulfides contain an average of 1.11 wt. % Zn and are up to 300 μm in diameter. Sulfide blebs locally contain micrometer-size inclusions and veinlets of native metals, such as Ni, and inclusions of glass or quartz (Figure 11). The low analytical totals from electron-microprobe analyses may be partially due to the tiny inclusions of glass or quartz. Many sulfides were analyzed for oxygen using the electron microprobe. The sulfides contained up to 9.89 wt. % O suggesting the low totals may also be related to the presence of oxides. The sulfides display small-scale exsolution, which is similar to the Vermont samples (Figure 12).

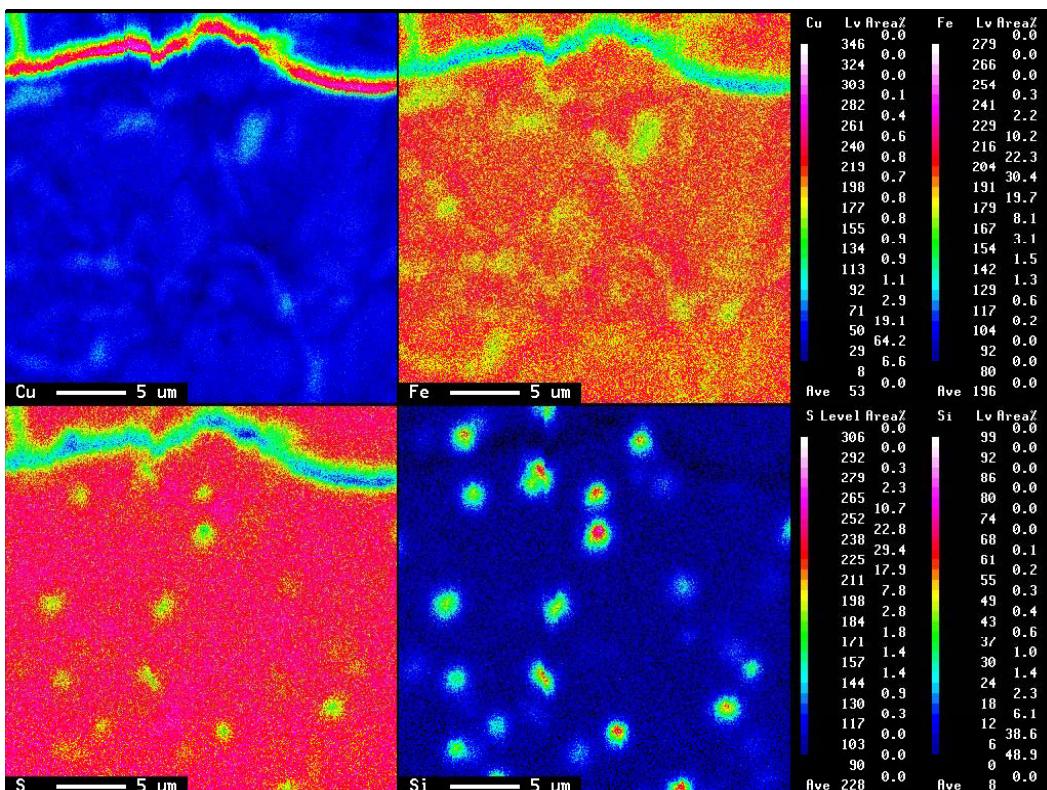

Figure 11. Electron-microprobe map illustrating the distribution of Cu, Fe, S, and Si in a sulfide bleb in granulated slag sample 01CB25 from Ducktown. Warmer colors indicate higher concentrations; cooler colors indicate lower concentrations.

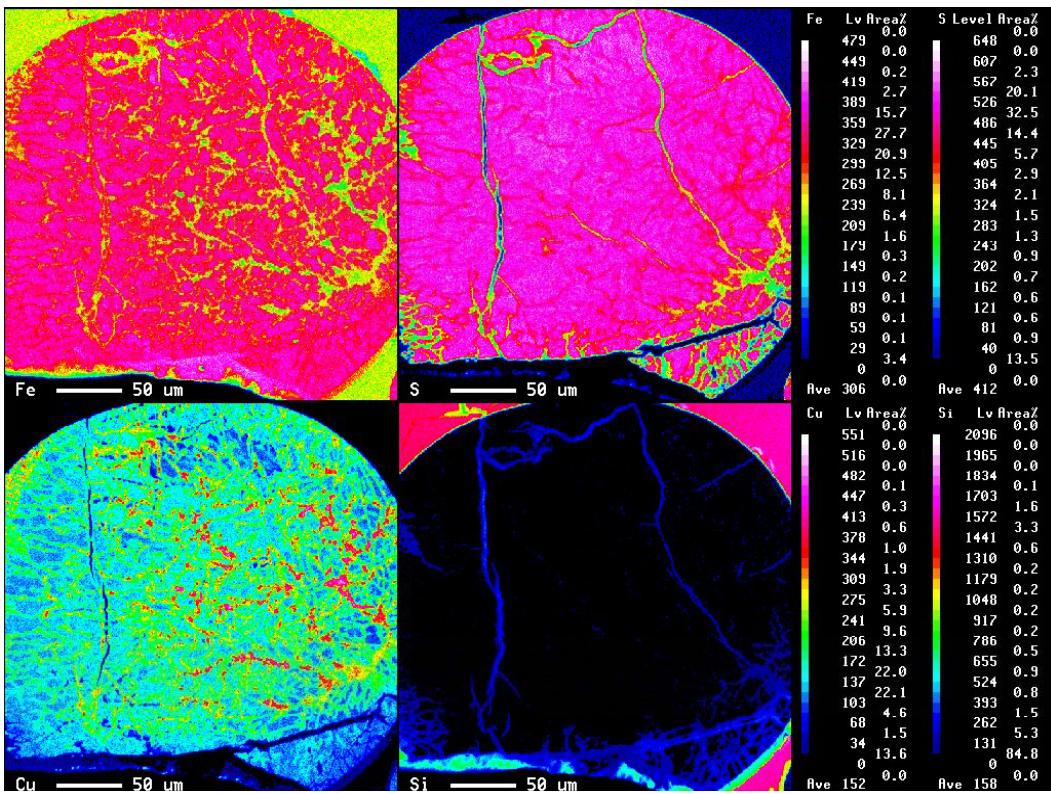

Figure 12. Electron-microprobe map illustrating the distribution of Fe, S, Cu and Si in a sulfide bleb in granulated slag sample 01CB25 from Ducktown. Warmer colors indicate higher concentrations; cooler colors indicate lower concentrations.

Calcine

The calcine sample from the Ducktown mining district is dark red and composed of silt-sized grains (Figure 2D). The sample is mainly hematite, with lesser quartz, spinel, sulfides, gypsum, and minor chlorite and biotite. The hematite is highly porous and occurs as rounded to sub-angular fragments ranging from a few micrometers to 100 μm in diameter.

Clayton smelter site

The air-cooled slag from the Clayton smelter site is texturally similar to the Vermont copper belt slag. Both display flow textures, and have glassy chilled margins containing vesicles, and coarse-grained crystalline interiors. The phases present are olivine, pyroxene, glass, spinel, sulfides, alloys, and native metals. The olivine crystals are commonly randomly oriented laths up to several centimeters long (Figure 9E and F). The composition of the olivines (Figure 7) falls between fayalite and kirschsteinite based on electron-microprobe analyses (Table 3). The olivine-group minerals also contain minor Mn (up to 3.32 wt. % MnO), Mg (up to 2.72 wt. % MgO) and Zn (up to 1.25 wt. %

ZnO). Several of the laths are zoned with the interior being slightly enriched in Ca and Mg (Table 3). The subhedral pyroxenes are shown in Figure 9E and F. Pyroxene is hedenbergitic in composition and contains an average of 6.64 wt. % Al_2O_3 , 0.83 wt. % MnO , and 0.70 wt. % ZnO (Figure 13 and Table 3).

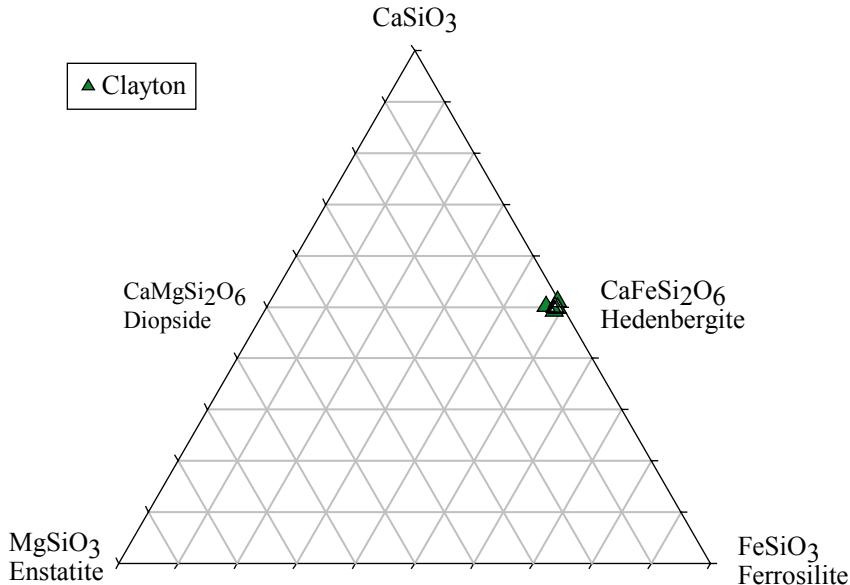

Figure 13. Composition of pyroxene in Clayton smelter slag on a MgSiO_3 - FeSiO_3 - CaSiO_3 ternary diagram.

The glass phase in the Clayton smelter slag is interstitial and the composition can be characterized as $\text{SiO}_2 > \text{FeO} \geq \text{CaO} > \text{Al}_2\text{O}_3$ (Figure 5 and Table 4). The composition of interstitial glass in the Clayton smelter slag is similar to the composition of interstitial glass in the slag from the Vermont copper belt samples, although it contains higher concentrations of Ca and lower concentrations of Al (Figure 5). The interstitial glass also contains minor Pb (average 4.26 wt. % PbO) and Zn (average 3.19 wt. % ZnO).

Subhedral to euhedral spinel up to 50 μm in diameter is found in the Clayton smelter slag (Figure 9E). The composition of spinel (Table 5 and Figure 8) is magnetite with up to 3.27 wt. % Al_2O_3 . The spinels also contain ZnO (average 1.31 wt. %) and TiO_2 (average 1.02 wt. %).

The sulfide minerals bornite-digenite, galena, and sphalerite/wurtzite $[(\text{Fe}, \text{Zn})\text{S}]$ occur either as discrete grains or as admixtures with metallic phases such as Sb, Cu, Pb, and alloys of various metals including Pb, Sb, Cu, Fe, As, and Ag (Table 6). Metallic Pb and sphalerite/wurtzite were identified qualitatively using SEM. These admixtures are up to several hundred micrometers in diameter and display myrmekitic textures and micrometer-scale exsolution features (Figure 9F, and Figure 14). Figure 14 illustrates the composition of a detailed section of one of these complex polymineralic blebs. Because of the fine-grained exsolved nature of the material, analyses may represent admixtures of phases.

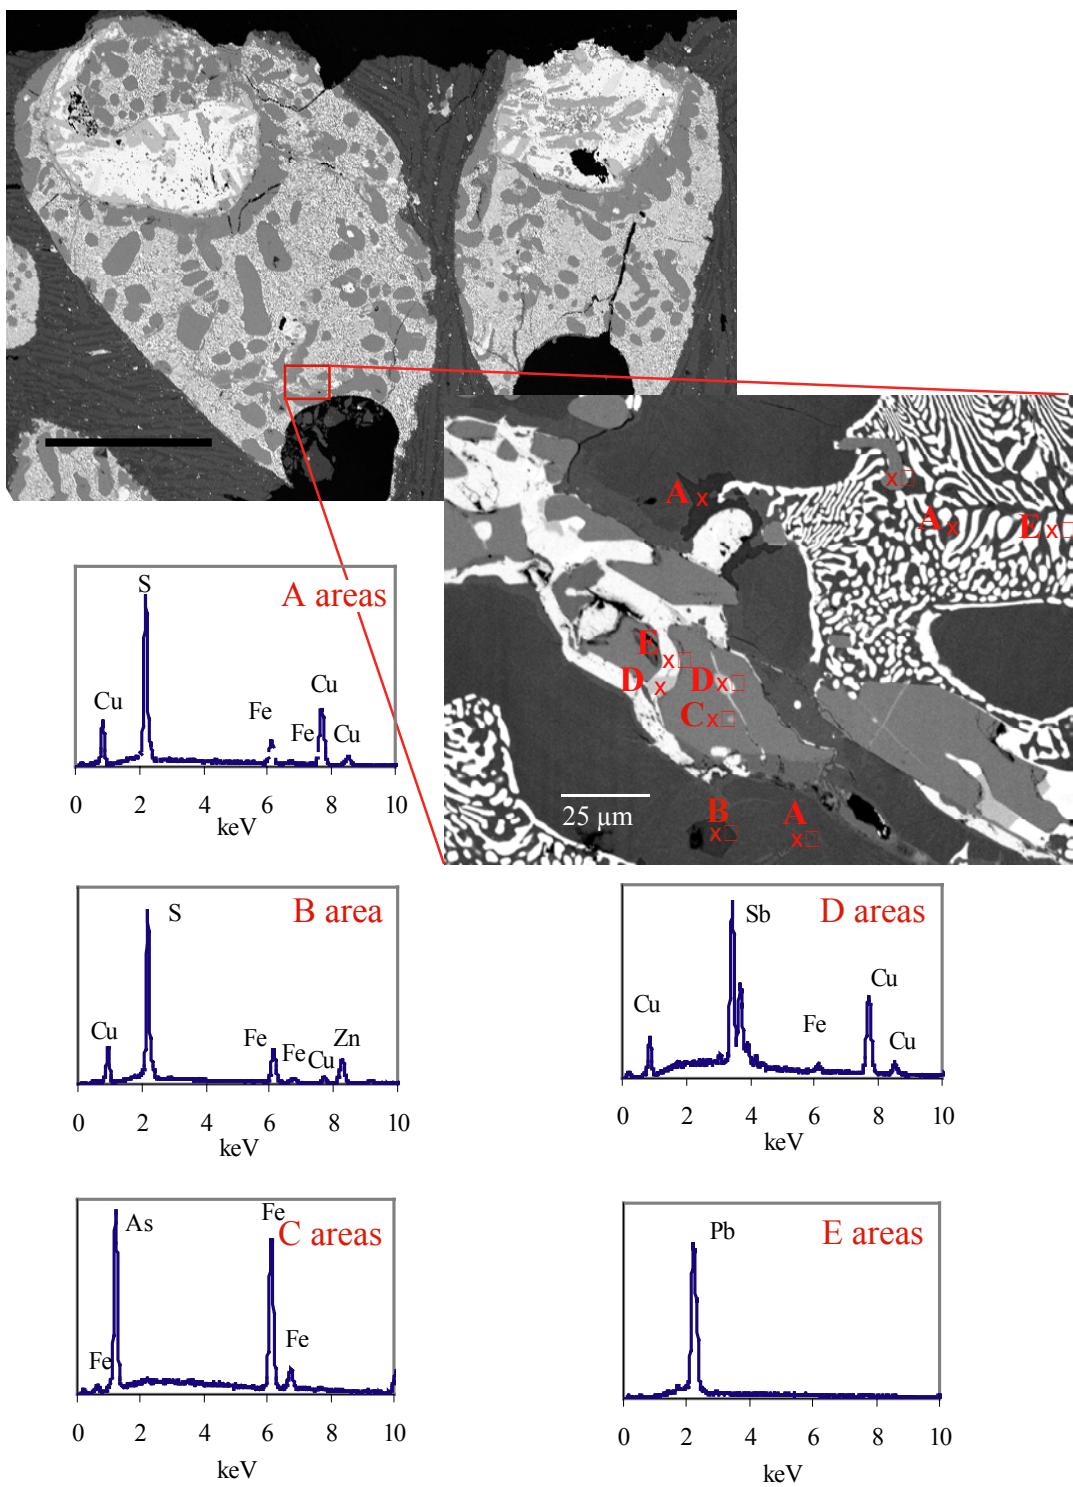

Figure 14. Backscatter scanning electron photomicrographs of a large polymineralic particle in the Clayton smelter slag (sample 53JH00). The energy-dispersive spectra shown are for areas outlined in the close-up view of larger blebs.

Secondary Mineralogy

The slag and other waste rock historically have been and currently are subjected to weathering. The reactivity of this material is evident in the formation of secondary minerals on these samples. Samples from a slag pile at the Ely mine contain crystalline and amorphous secondary mineral and include chalcanthite (Figure 15A and B), rozenite, siderotil, jarosite, brochantite, gypsum, and amorphous Fe and Al hydroxides. Minerals such as jarosite, gypsum, and amorphous Al and Fe coatings are shown on this same slag pile at the Ely mine in Figure 15C. Secondary mineral growths were also seen on the granulated slag pile at Ducktown and the weathered surface consists of jarosite and gypsum as shown in Figure 15D.

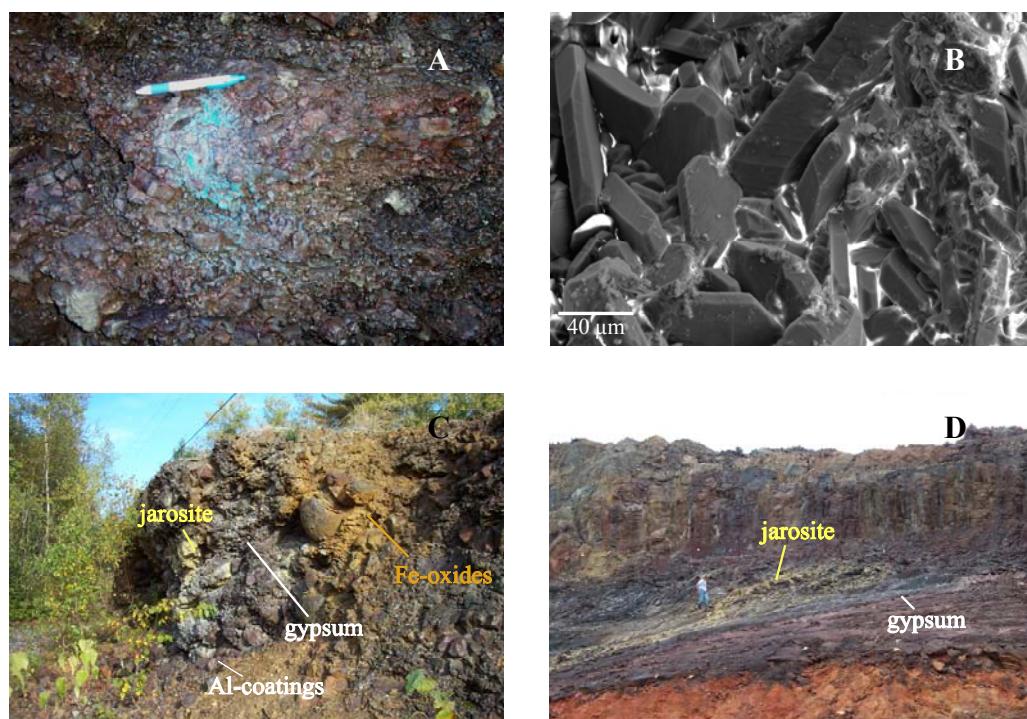

Figure 15. Photographs and a photomicrograph illustrating secondary mineral growths on pot slag at the Ely mine and granulated slag at Ducktown. A. Outcrop of pot slag at the Ely mine, showing surficial growths of chalcanthite (blue salt). B. Backscatter scanning electron photomicrograph of chalcanthite crystals. C. Weathered surface of Ely slag showing jarosite, gypsum, Fe-oxides, and Al-coatings. Note pot casts. D. Weathered surface of granulated slag at Ducktown showing jarosite and gypsum.

LEACHATE DATA

Leaching tests conducted on crushed splits (<2 mm in diameter) with deionized water (DIW) and eastern synthetic precipitation (ESP) indicate that significant concentrations of metals can be released from the slag and waste rock. The

concentrations of most major elements in the DIW leachate and ESP leachate are similar except for Al, which is leached more readily by ESP than by DIW for most samples. In general, the concentration of trace elements in leachate produced by ESP (pH=4.1) is equal to or higher than those in leachate produced by deionized water (pH=5.0) (Table 7). For example, the concentration of Cu in DIW leachate is the same as in the ESP leachate for the calcine sample from Ducktown (01CB23) using the ICP-MS data. Whereas, the concentration of Cu in DIW leachate is less than half of that in the ESP leachate for the slag sample 01JH28rind from the Elizabeth mine. The final pH of the DIW leachate is higher than that of the ESP leachate for all samples except for 98JHNPB-s, 01JH28core, and 53JH00. Also, the specific conductance of all samples (except 01JH27) is lower in leachate produced by DIW than in leachate produced by ESP.

The major anion in the leachate for all samples is sulfate. The cations are dominated by Si, Ca, K, Na, and Mg; Al, Fe, and Cu are significant in a few samples. The highest concentration of Ca (180 mg/L) is found in leachate from the Ducktown calcine, whereas the highest concentration of Fe (60 mg/L) is found in leachate from the Ely sintered waste rock (Table 7). The concentrations of trace elements in the leachates vary from sample to sample as illustrated in Figure 16. For example, the concentrations of Cu range from 19 to 21,000 µg/L. All of the concentrations of Cu in leachate are greater than the chronic and acute water-quality guidelines for the protection of aquatic life (assuming a hardness of 100 mg/L CaCO₃) as shown in Figure 16A (U.S. E.P.A., 1993). The highest concentration of Cu is found in leachate from waste rock (sample 01JH31B from the Ely mine). This sample also contains the second highest concentration of Cu (11,500 mg/kg) in the bulk chemical analysis. The concentration of Zn in the leachate (Figure 16B) in most samples is higher than the acute and chronic toxicity guidelines for the protection of aquatic life. The highest concentration of Zn (3,900 mg/L) in leachate from the Ducktown calcine (01CB23) is nearly an order of magnitude greater than the concentration of Zn in the other leachates. There is no U.S. E.P.A. toxicity guideline established for Co, but the concentration of Co in many leachates exceeds the New York water criterion (Figure 16C). Also, the concentrations of Cd and Fe in many leachates are higher than the chronic toxicity guidelines for aquatic life (Figure 16D and E). In contrast, the concentrations of Pb and Ni are not significant for most samples (Figure 16F and G). However, the concentration of Pb in the leachate from the Clayton smelter slag exceeds water-quality guidelines for the protection of aquatic life by several orders of magnitude. The leachate from this slag also contains the highest concentrations of As (52 µg/L), Ba (5.8 µg/L), Mn (140 µg/L), and Sb (290 µg/L).

Table 7. Analytical results of leaching tests. See Crock and others (1999) for explanation of methods.

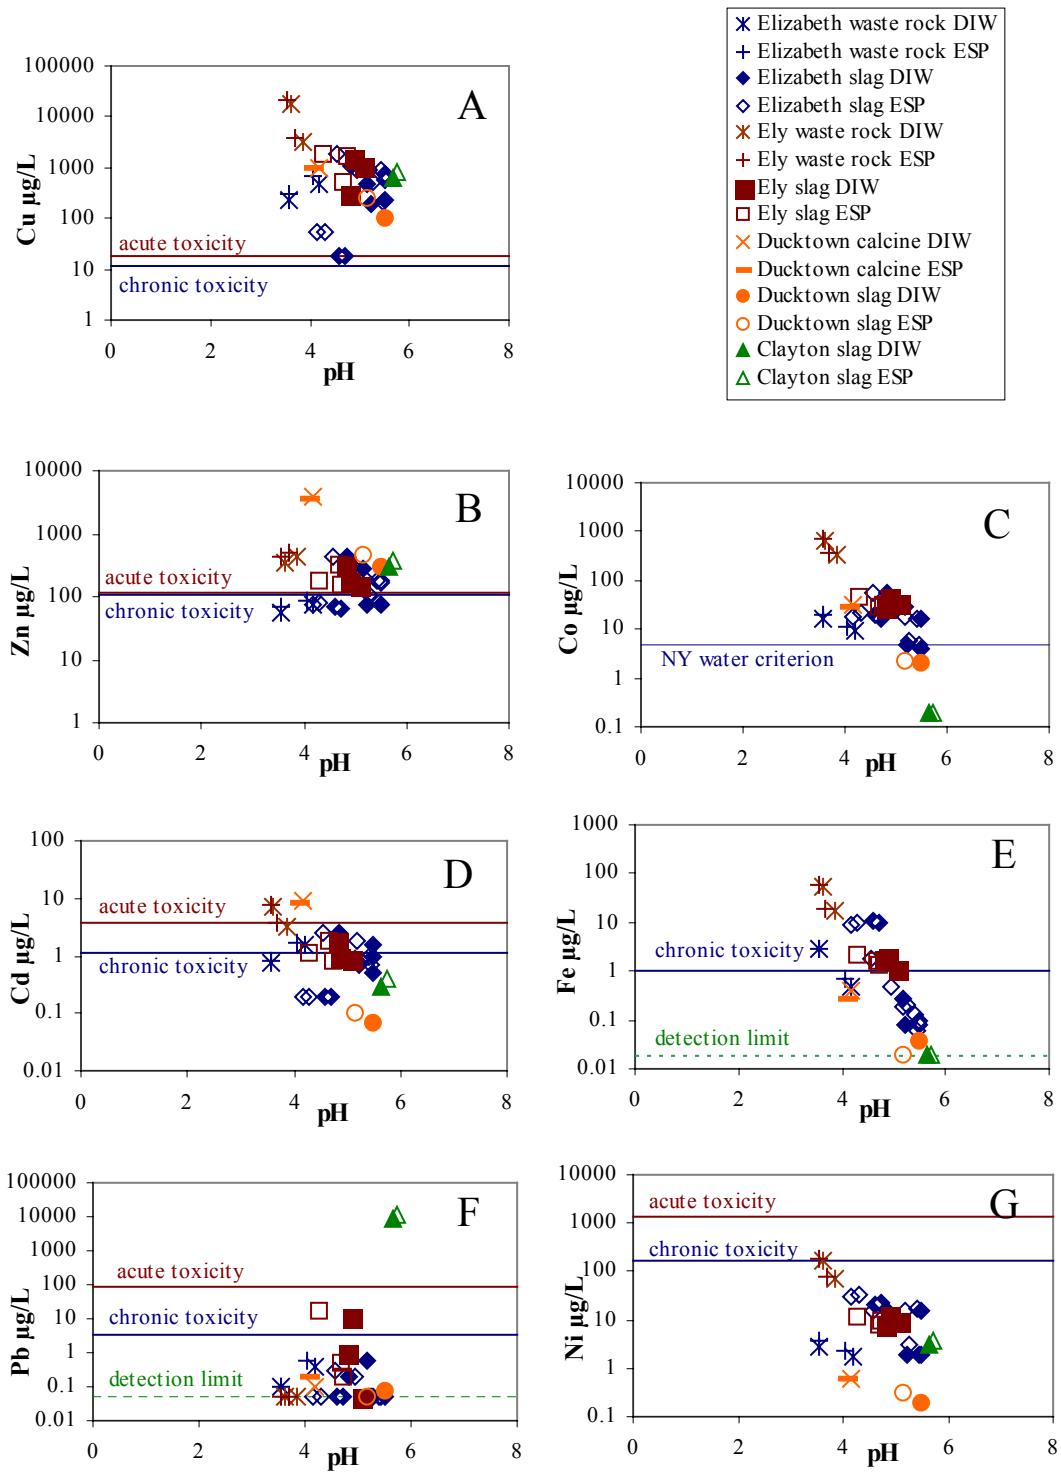

Figure 16. Concentration of A. Cu, B. Zn, C. Co, D. Cd, E. Fe, F. Pb, and G. Ni in leachates. Leaching tests were performed using deionized water (DIW) and eastern synthetic precipitation (ESP). Water-quality guidelines for the protection of aquatic life (U.S. E.P.A., 1993) based on an assumed hardness of 100 mg/L CaCO_3 are labeled for all elements except Co, for which the N.Y. water criterion is labeled.

ACKNOWLEDGMENTS

The authors would like to thank Ed Hathaway and Bill Lovely of the U.S. Environmental Protection Agency and Scott Acone of the U.S. Army Corps of Engineers for their assistance and cooperation. The manuscript benefited from discussions with Matthew Kierstead, PAL, Inc, and Carter Hearn, U.S. Geological Survey. Harvey Belkin provided guidance on SEM and electron-microprobe operations. We also thank Tom Moyer, Science Applications International Corporation, and David Williams, U.S. Environmental Protection Agency. Carter Hearn and John Mars of U.S. Geological Survey provided thoughtful reviews of the manuscript.
